

LLM Pipeline for Hierarchical Narrative Classification: A Traceable Approach to Multilingual Propaganda Detection

Anonymous submission

Abstract

This paper presents Agora, a configurable and reproducible framework for robust hierarchical multi-label classification using large language models. We address critical reliability challenges in LLM-based classification through a multi-agent ensemble approach with voting consensus and an optional actor-critic self-refinement loop. Our system decomposes the hierarchical classification task into manageable steps via a state-graph pipeline, providing enhanced traceability for multilingual propaganda detection. We evaluate our approach on hierarchical narrative classification benchmarks, demonstrating improved robustness and consistency compared to baseline LLM approaches.

Keywords: hierarchical classification, propaganda detection, narrative analysis, large language models, multilingual NLP

1. Introduction

Text Classification (TC) is a foundational task in Natural Language Processing (NLP) (Zangari et al., 2024). While traditional approaches often model TC as a single-label problem, real-world texts frequently contain multiple overlapping themes, motivating the use of Multi-Label Classification (MLC) (Hu et al., 2025; Tidake and Sane, 2018). A particularly challenging yet crucial variant is Hierarchical Multi-Label Classification (HMLC), where labels are organized in a predefined hierarchy (e.g., a tree or DAG) (Liu et al., 2023). This structure is common in domains requiring nuanced analysis, such as misinformation detection, where identifying nested propaganda narratives is a key challenge.

The advent of Large Language Models (LLMs) has opened new frontiers for HMLC, enabling powerful zero-shot classification without extensive labeled data. However, this power comes with significant reliability challenges. LLMs are known to be stochastic, producing different outputs for the same input, and often exhibit low instruction fidelity, failing to consistently adhere to complex hierarchical constraints or output formats (Qin et al., 2024). These limitations hinder their deployment in high-stakes applications where robustness and verifiable reasoning are paramount.

To address these shortcomings, we introduce Agora, a multi-agent ensemble framework that significantly improves the robustness and accuracy of Large Language Models on complex Hierarchical Multi-Label Classification tasks. By aggregating parallel classifications from multiple LLM agents via voting, Agora mitigates the inherent stochasticity of LLMs and produces more reliable results than a standard single-agent approach.

2. Related Work

2.1. Traditional Multi-Label Classification Approaches

The core challenge in Multi-Label Classification (MLC) has historically been the effective modeling of inter-label dependencies. Early problem-transformation methods sought to adapt single-label algorithms to this task. Approaches ranged from Binary Relevance, which simplifies the problem by training an independent classifier for each label but ignores correlations, to Classifier Chains, which attempt to capture dependencies by feeding the predictions of one classifier as features to the next in a sequence (Zhang et al., 2018; Read et al., 2011). While foundational, these methods were often superseded by deep learning models, particularly Transformers, which could learn complex label correlations implicitly from large datasets (Devlin et al., 2019).

2.2. Hierarchical Multi-Label Classification

For the more specific task of Hierarchical Multi-Label Classification (HMLC), research focused on creating architectures that explicitly leverage the label taxonomy. A dominant paradigm involved coupling a Transformer-based text encoder with a Graph Neural Network (GNN) that operates on the label graph, allowing the model to learn hierarchy-aware representations and enforce structural consistency (Zhou et al., 2020; Xu et al., 2021). However, the advent of Large Language Models (LLMs) has again shifted the landscape, enabling powerful zero-shot HMLC capabilities that bypass the need for complex, task-specific architectures and extensive supervised training (Wang et al., 2023).

2.3. Zero-Shot LLM Approaches and Current Challenges

The recent SemEval-2025 Task 10 on narrative detection serves as a clear benchmark for this modern, LLM-driven approach. State-of-the-art systems effectively use techniques like retrieval-augmented generation and specialized prompting to classify texts within the task’s two-level hierarchy (Singh et al., 2025; Younus and Qureshi, 2025). In our own prior work, we introduced a modular “agentic” framework that decomposed the task into parallel binary decisions (Eljadiri and Nurbakova, 2025). Yet, these pioneering systems share a common vulnerability: their reliance on a single, non-deterministic generative pass, which exposes them to the inherent stochasticity of LLMs. While ensembling is a classic technique for improving robustness in supervised models (Jurkiewicz et al., 2020), its systematic application to mitigate the unreliability of zero-shot LLMs in HMLC remains underexplored. Our work directly addresses this gap, proposing a multi-agent ensemble framework to produce stable, consensus-driven classifications.

3. System Architecture

Our investigation into a robust zero-shot HMLC framework followed an iterative design process. We began by analyzing a promising top-down prompting approach, then developed a traceable self-refining pipeline, and finally, upon identifying its limitations, engineered a more robust multi-agent ensemble.

3.1. Baseline Inspiration: Top-Down Zero-Shot Classification

A promising recent approach to HMLC, which we refer to as H3Prompting, was introduced by Singh et al. (2025). This method decomposes the hierarchical classification task into a sequence of zero-shot LLM queries, where an initial prompt determines the top-level category, and subsequent prompts classify second-level narratives conditioned on the first-level prediction. In the spirit of reproducible research, we first aimed to replicate this method. However, the lack of publicly available implementation details prevented a direct reproduction, motivating our development of an open and configurable framework to systematically investigate zero-shot HMLC strategies.

3.2. Initial Approach: The Traceable Actor-Critic Pipeline

Our first architectural exploration, the Actor-Critic Pipeline, sought to improve the reliability and transparency of a single agent’s output. While zero-

shot classification is powerful, simple label outputs lack traceability, making them difficult to audit and susceptible to unverified hallucinations. To overcome this, we designed a multi-stage pipeline that reframes the task from simple classification to evidence-grounded claim generation and validation.

Our implementation uses the LangGraph framework to structure the process as a cyclical state graph (LangChain AI, 2024a). The pipeline configuration is managed by a `ConfigurableGraphBuilder`, allowing components like validation to be enabled or disabled and different LLMs to be assigned to specific nodes via a YAML file. The workflow proceeds through several stages, as illustrated in Figure 1.

3.2.1. Category Classification

An initial node determines the document’s high-level topic (e.g., CC or URW) to focus subsequent stages on the relevant subset of the narrative taxonomy.

3.2.2. The Narrative Actor (Claim Generation)

The “Actor” is an LLM agent prompted to act as an expert analyst. For each narrative it identifies, it must generate a structured JSON object containing the `narrative_name`, a verbatim `evidence_quote` from the text, and reasoning that connects the two.

3.2.3. The Narrative Critic (Claim Validation)

The Actor’s output is passed to the “Critic,” a separate LLM agent with a distinct, skeptical persona. The Critic validates the Actor’s claims against strict criteria (evidence accuracy, relevance, completeness). If the Critic finds flaws, it generates structured feedback, and the graph’s conditional logic routes the state back to the Actor for a retry, incorporating the feedback into a refinement prompt.

3.2.4. Sub-narrative Actor and Critic

Once narratives are approved, the process repeats hierarchically. A Sub-narrative Actor generates claims for each parent narrative, which are then validated by a Sub-narrative Critic, also with a self-correction loop.

This evidence-grounded architecture offers significant advantages in traceability and auditability, as every prediction is grounded in a textual `evidence_quote`, a process we enhanced using LangSmith for detailed debugging and prompt refinement (LangChain AI, 2024b). However, while this pipeline showed promise, our experiments revealed that it introduced its own form of instability. The process was highly sensitive to the quality of

Figure 1: Actor-Critic validation pipeline architecture. The system decomposes HMLC into hierarchical stages where a Narrative Actor generates evidence-grounded claims, which are then validated by a Narrative Critic. Feedback loops enable iterative refinement before progressing to sub-narrative classification.

the Critic’s feedback, which, being LLM-generated,

was itself prone to stochasticity. A flawed critique could send the Actor down an unproductive refinement path, sometimes degrading performance. This reliance on a single, fallible “critic” highlighted a fundamental bottleneck and motivated our shift towards a more robust consensus mechanism.

3.3. Proposed Framework: The Agora Multi-Agent Ensemble

To overcome the limitations of a single-critic system and the broader issue of single-agent stochasticity, we developed Agora, a multi-agent ensemble framework. The core principle of Agora is to replace the judgment of a single agent (or a single critic) with the collective “wisdom of the crowd,” leveraging the consensus of multiple independent agents to arrive at a more stable and accurate classification.

The framework operates via a fan-out, fan-in process for each level of the hierarchy (e.g., Narrative classification).

3.3.1. Fan-Out (Parallel Classification)

Instead of a single LLM call, Agora instantiates N independent agents (where N is a configurable parameter). The same input text and prompt are sent to all N agents, who perform the classification in parallel. This step effectively samples N independent points from the LLM’s output distribution for the given task.

3.3.2. Fan-In (Aggregation via Voting)

After all N agents return their individual classifications, an Aggregation node consolidates the results using a voting scheme. We implemented and evaluated three distinct aggregation strategies:

- **Union:** The final label set includes any label proposed by at least one agent. This high-recall strategy is useful for identifying all potential labels.
- **Intersection:** The final label set includes only those labels that all agents unanimously agreed upon. This high-precision strategy filters out all but the most confident predictions.
- **Majority Vote:** The final label set includes any label proposed by more than half ($> N/2$) of the agents. This strategy provides a robust balance between precision and recall, filtering out stochastic, outlier classifications while retaining a strong consensus.

This ensemble approach directly addresses the single-point-of-failure issue observed in the Actor-Critic pipeline. Instead of relying on one critic’s potentially noisy feedback, Agora relies on the statistical robustness of a majority decision, providing

a more reliable and conceptually simpler method for improving classification quality.
